**Abstract.** In this study, on-site testing was carried out to investigate the vibration performance of a composite steel-bar truss slab with steel girder system. Ambient vibration was performed to capture the primary vibration parameters (natural frequencies, damping ratios, and mode shapes). The composite floor possesses low frequency (< 10 Hz) and damping (< 2%). Based on experimental, theoretical, and numerical analyses on natural frequencies and mode shapes, the boundary condition of SCSC (i.e., two opposite edges simply-supported and the other two edges clamped) is deemed more reasonable for the composite floor. Walking excitations by one person (single excitation), two persons (dual excitation), and three persons (triple excitation) were considered to evaluate the vibration serviceability of the composite floor. The measured acceleration results show a satisfactory vibration perceptibility. For design convenience and safety, a crest factor  $\beta_{rp}$  describing the ratio of peak acceleration to root-mean-square acceleration induced from the walking excitations is proposed. The comparisons of the modal parameters determined by ambient vibration and walking tests reveal the interaction effect between the human excitation and the composite floor.

Keywords: steel-bar truss slab; composite floor; human-structure interaction; vibration serviceability; crest factor

#### 1. Introduction

In recent years, the composite steel-concrete system has been widely used in buildings (Ferrer *et al.* 2018, Gou *et al.* 2018, Hadjioannou *et al.* 2018, Kataoka *et al.* 2017, Kimani and Kaewunruen 2017, Kyvelou *et al.* 2018, Quang *et al.* 2018, Wang 2005), infrastructures, footbridges (Gonilha *et al.* 2014), and bridges (Madrazo-Aguirre *et al.* 2015), as the longer span and lighter structural form has become a trendy design choice. The composite steel-bar truss slab (CSTS) with steel girder system shown in Fig. 1 is one kind of novel composite structures, which includes the slab consisting of a steel truss system (JG/T 368-2012 2012) with top, bottom and web reinforcing bars (Fig. 1(a)), baseplate, and steel girder (Fig. 1(b)).

In reviewing the relevant literature, the CSTS system has the following advantages (Colajanni *et al.* 2017, Wang *et al.* 2015, 2016, 2017b):

- (1) Reasonable stress level and good economy;
- (2) Suitable for long-span floor systems and convenient for construction:
- (3) Reduction in construction time and labor cost; and
- (4) Good crack and fire resistances.

Applications of the CSTS system can be extended to

\*Corresponding author, Post-Doctor,

school buildings, movie theaters, prefabricated buildings, and industrial factories. Some issues concerning the static and dynamical performances of the CSTS system have been studied, including cracks and bearing capacity (Li et al. 2012), fire resistance (Wang et al. 2015), short-term rigidity (Cheng et al. 2013), structural failure (Huang et al. 2005), shear connection capacity (Colajanni et al. 2017), and seismic behavior (Wang et al. 2017a). However, it has been known that the design of a long-span and light structure (e.g., CSTS with steel girder) is often governed by a serviceability requirement rather than the strength one (Van Nimmen et al. 2017, Zhou et al. 2016). One of the important serviceability requirements is the acceptance/ perception of the vibration caused by human activities (Votsis et al. 2017, Nguyen et al. 2012) such as walking, running, and aerobics dancing, which should be considered to prevent the functionality of the structure from being compromised by excessive vibrations. This issue has not been fully understood for a CSTS with steel girder. Vibration serviceability problem may arise if the vibration amplitude is beyond a certain limit, annoying the occupants and affecting the vibration-sensitive equipment. Hence, a further investigation on human vibrations in the CSTS with steel girder is warranted. Specifically, the modal parameters and acceleration response were examined.

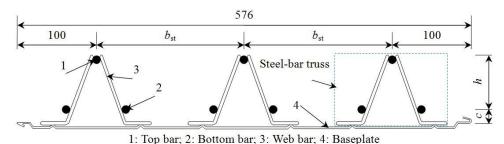

The objectives of this study are:

- To analyze the data measured from ambient vibration and then to ascertain the modal parameters and boundary conditions;
- To analyze the data measured from walking vibrations (including single, dual, and triple

excitations) and then to evaluate the vibration serviceability;

- To compare the modal parameters obtained from the ambient and walking vibrations and to verify the human-structure interaction effect;
- To propose the crest factor  $\beta_{rp}$  for calculating the root-mean-square (RMS) acceleration.

# 2. Description of prototype floor and accelerometer layout

In-situ test is a practical way to study the vibration performance of the CSTS with steel girder under human daily activities and to determine its dynamic properties (Chen et al. 2014, Fahmy and Sidky 2012). The investigated CSTS with steel girder in this study was intended to be used in meeting rooms, which locates in Yongchuan, Chongqing, China. The CSTS with steel girder had been designed to meet the usual building requirements including structural safely, fire resistance, and maximum deflection. The structural arrangement and cross section of the investigated composite floor is shown in Fig. 2, and the on-site view of the composite floor is shown in Fig. 3. The thickness and material specification for the steel-bar truss slab are listed in Table 1 and the detailed cross sections and yield strength for H-shaped steel girders are indicated in Table 2. The elasticity modulus of concrete is  $3.00 \times 10^4$ MPa. The composite floor was completed prior to the installation of any nonstructural component (e.g., ceiling, duct, mechanical equipment, and partition).

Fig. 2(a) shows the schematic accelerometer locations along with a coordinate system used to obtain the dynamic characteristics and vertical acceleration response of the

composite floor, where  $A_{ij}$  (i = 1-8, j = 1-9) represents the *j*th accelerometer location for the *i*th test. From the figure, it is known that 72 accelerometers would be needed for oneoff measurement. However, the monitoring system used in this study consists of only ten accelerometers DH610V ranging  $\pm 5$  g maximum (g being the gravitational acceleration) and a data acquisition system DH5922N (Fig. 3). To overcome the problem, the accelerometers were utilized eight times and the measurement point  $A_{45}$  was selected as the stationary location at all time. For example, after the first measurement, the accelerometers were moved from  $A_{1j}$  to  $A_{2j}$  (j = 1-9). The data acquisition system was used to sample all the results collected from these accelerometers at

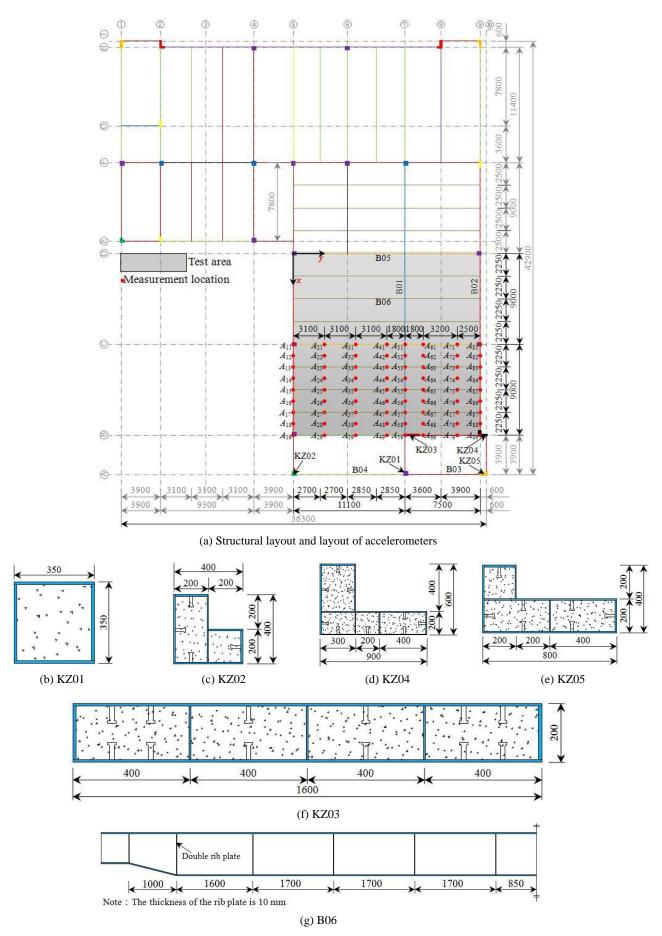

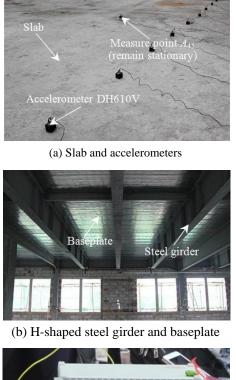

Fig. 2 The structural arrangement and cross section of composite floor and layout of accelerometers (unit: mm)

(c) Data acquisition system DH5922N

1000 Hz. Before each formal test procedure, a preloading was performed to determine an appropriate acceleration range for recording the acceleration response.

### 3. Modal analysis

To ascertain the important parameters of assessing the vibration serviceability, i.e., natural frequency, mode shape, and damping ratio, the ambient vibration method is needed. For an arbitrary row of accelerometers ( $A_{i1} - A_{i9}$ , i = 1-8), the duration time is 300s. The enhanced frequency domain decomposition (EFDD) method has been used to processes the test data (Altunisik *et al.* 2011, Pioldi and Rizzi 2018).

The first three vertical mode shapes of the composite floor are shown in Fig. 4 and the measured natural frequencies and damping ratios for the first three vibration modes are summarized in Table 3. As noted, these frequencies are less than 10 Hz, indicating that the composite floor is relatively flexible (Smith *et al.* 2009). The measured critical damping ratio for the composite floor is 2.00% which is consistent with the value suggested by the AISC (Murray *et al.* 2016).

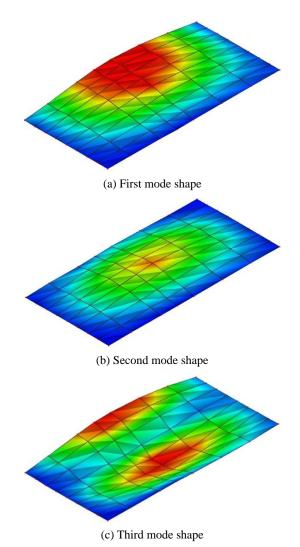

Fig. 4 The first three mode shapes of composite floor

Table 3 Measured natural frequencies and damping ratios of the composite floor for the first three vibrations modes

| The <i>i</i> th mode | Natural frequencies (Hz) | Damping ratio (%) |
|----------------------|--------------------------|-------------------|
| 1                    | 5.31                     | 2.00              |
| 2                    | 6.59                     | 0.50              |
| 3                    | 9.46                     | 0.60              |

#### 4. Boundary conditions

Both numerical and theoretical methods were used to determine a reasonable boundary condition for the composite floor. In the numerical simulation, the entire structural system (Fig. 5) was modeled, in which C3D20 element (20-node quadratic brick) available in ABAQUS program were used and the total number of element is 25484. In the theoretical analysis, the composite floor was idealized as an orthotropic plate (Zhang *et al.* 2017), where the *i*th natural frequency  $f_i$  can be determined by the Rayleigh principle (Timoshenko and Woinowsky-Krieger 1959)

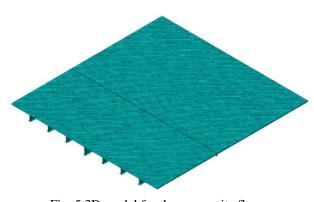

Fig. 5 3D model for the composite floor

|                    | 3 | 9.870         | 150.064       | 1.000         | 22.270        |

\*Notes: SCSC: two opposite edges simply supported and the other two edges clamped; CCCC: all four edges clamped

$$f_{i} = \frac{1}{2\pi} \frac{\alpha_{0i}}{b^{2}} \sqrt{\frac{g}{q_{0}}} \sqrt{\alpha_{1i} \frac{D_{1}}{C^{4}} + \alpha_{2i} D_{2} + \alpha_{3i} \frac{D_{3}}{C^{2}}}$$
(1)

where C = a/b with a = plate width and b = beam span;  $D_1$ and  $D_2$  are the plate stiffnesses in x and y directions, respectively;  $D_3$  is the combined rigidity; and  $q_0$  is the weight per unit area of the plate; and  $\alpha_{0i}$ ,  $\alpha_{1i}$ ,  $\alpha_{2i}$ , and  $\alpha_{3i}$  are the coefficients depending on the boundary condition (Table 4). It should be noted that the boundary conditions listed in Table 4 are in accordance with the convention defined in Fig. 6 and that the vibration mode functions for boundary conditions "CC" and "SS" are described in Table 5.

According to the literatures (Smith *et al.* 2009, Timoshenko and Woinowsky-Krieger 1959) and Fig. 2(a), the coefficients  $D_1, D_2, D_3$  and  $q_0$  in Eq. (1) were determined

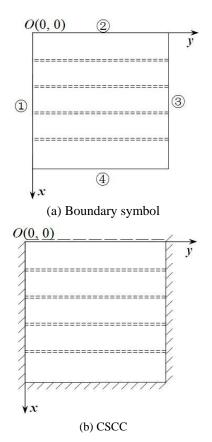

Fig. 6 The naming conventions on the boundary condition of the composite floor

as  $4.32 \times 10^{6}$  N·m,  $5.01 \times 10^{8}$  N·m,  $4.46 \times 10^{6}$  N·m, and 3658.90 N/m<sup>2</sup>, respectively. Table 6 lists the first three natural frequencies obtained analytically and numerically under different boundary conditions and the errors with the measured values (Table 3). Considering the beam-slab stiffness ratio and the effect of adjacent structure (Zhou et al. 2017), the boundary condition of "CCCC" or "SCSC" was assumed first for the composite floor. The mode shape of the composite floor with SCSC edges are shown in Fig. 7. As noted, under the boundary conditions "CCCC" the error from either the analytical or the finite element method is quite high. While, under the boundary condition "SCSC" the error is relatively small and both methods yield virtually the same results. Consequently, the boundary condition "SCSC" is deemed more reasonable in performing a theoretical or numerical vibration analysis.

Table 5 Vibration mode functions for boundary conditions "CC" and "SS"

|                    |   |   |                  |   |                    | k <sub>i</sub>     |                        | a   |  |
|--------------------|---|---|------------------|---|--------------------|--------------------|------------------------|---|--|
| Boundary condition |   |   |                  | Vibration mode function -   | 1 2 <i>j</i> >2    |                    | <i>j</i> > 2           | - Coefficient $\gamma_j$                                    |  |
| CC                 |   | L |                  | $W_j(z) = \sin k_j z$   | $\frac{\pi}{L}$    | $\frac{2\pi}{L}$   | $\frac{j\pi}{L}$       |   |  |
| SC                 | ¥ | L | $\mathbf{h}_{m}$ | $W_{j}(z) = \sin k_{j}z - \sinh k_{j}z$ $-\gamma_{j}(\cos k_{j}z - \cosh k_{j}z)$ | $\frac{4.7300}{L}$ | $\frac{7.8532}{L}$ | $\frac{(2j+1)\pi}{2L}$ | $\frac{\sin k_j L - \sinh k_j L}{\cos k_j L - \cosh k_j L}$ |  |

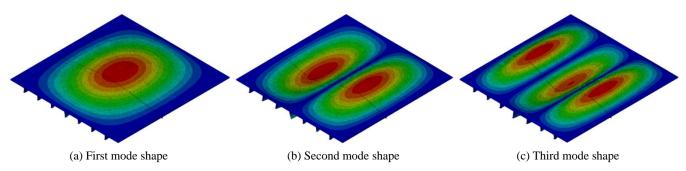

Fig. 7 The first three mode shapes of composite floor with SCSC edges

In order to further illustrate the suitability of boundary condition "SCSC", the modal assurance criterion (MAC) (Eq. (2)) (Xiong *et al.* 2018, Yashar *et al.* 2018) was adopted to analyse the correlation among the experimental, analytical, and numerical mode shapes.

$$MAC_{ij} = \frac{\left|\phi_i^{T} \tilde{\phi}_j\right|^2}{(\phi_i^{T} \phi_i)(\tilde{\phi}_i^{T} \tilde{\phi}_i)}$$
(2)

where  $\phi_i$  and  $\tilde{\phi}_j$  represent the *i*th and *j*th (i = j = 1, 2, 3) experimental and theoretical/numerical mode shapes, respectively.

Table 7 lists the MAC values for the *i*th mode shape. The table results indicate that both the theoretical and numerical mode shapes agree well with experimental results.

Based on the above analysis, the reasonable boundary condition of SCSC (i.e., two opposite edges simply supported and the other two edges clamped) is confirmed to be reasonable for the composite floor.

Table 6 The analytical and numerical natural frequencies under different boundary conditions and their errors with the measured values

#### 5. Walking excitations

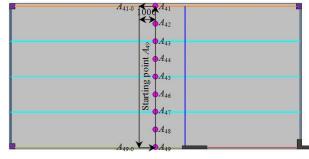

Human-induced vibration could be very complex, involving the magnitude of motion, surrounding environment, and human's perceptibility. A continuous steady-state motion may cause an annoying vibration. So, a series of walking tests were performed to estimate the vertical acceleration response and modal parameters of the

(a) Single excitation (walking route  $A_{49}$ - $A_{45}$ - $A_{41}$ )

(b) Dual excitation (walking route  $A_{49}$ - $A_{45}$ - $A_{41}$ )

(c) Triple excitation (walking route  $A_{49}$ - $A_{45}$ - $A_{41}$ )

Fig. 8 The walking route for triple excitation (route  $A_{49}$ - $A_{45}$ - $A_{41}$ , unit: mm)

composite floor. To better understand the vibration performance, the following three forms of steady-state excitations were considered: single excitation (done by one tester), dual excitation (done by two testers), and triple

(a) Single excitation

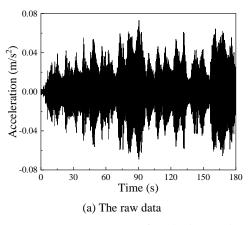

(b) Dual excitation

(c) Triple excitation

Fig. 9 The on-site views of walking excitations (mm)

excitation (done by three testers).

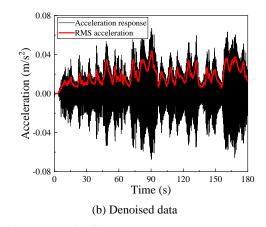

For the single excitation, three different persons weighted at 50 kg  $(N_{m1})$ , 56 kg  $(N_{m2})$ , and 74 kg  $(N_{m3})$ respectively were considered. Starting from  $A_{i9}$  (*i* = 4, 5, 6), each tester walked along the following routes repeatedly for a duration of 3 minutes:  $A_{i9} \rightarrow A_{i5} \rightarrow A_{i1} \rightarrow A_{i5} \rightarrow A_{i9} \rightarrow \dots$ , for example when i = 4, the route is shown in Fig. 8(a). For the dual excitation, the combinations of testers are indicated in Table 9. Starting from  $A_{i9}$  (i = 4, 5, 6), two testers spaced at 60 mm walked along the following routes repeatedly for duration of 3 minutes:  $A_{i9} \rightarrow A_{i5} \rightarrow A_{i1} \rightarrow A_{i5} \rightarrow A_{i9} \rightarrow \dots$ , for example when i = 4, the route is shown in Table 8(b). For the triple excitation, starting from  $A_{i9}$  (i = 4, 5, 6) in turn, each tester spaced 1000 mm from previous tester walked along the following routes repeatedly for a duration of 3 minutes:  $A_{i9} \rightarrow A_{i5} \rightarrow A_{i1} \rightarrow A_{i1\cdot 0} \rightarrow A_{i9\cdot 0} \rightarrow A_{i9} \rightarrow \dots$ , and it should be noted that the distance between  $A_{i1-0}$  (or  $A_{i9-0}$ ) to  $A_{i1}$  (or  $A_{i9}$ ) is 1000 mm, for example when i = 4, the route is shown in Fig. 8(c). Normal walking frequencies were recorded using a video device, Vidicon, as summarized in Tables 8, 9, and 10 for the three kinds of excitation, respectively. The on-site walking tests are shown in Fig. 9.

#### 5.1 Vibration serviceability evaluation

The response of the composite floor was evaluated in terms of peak and RMS accelerations. Although the peak acceleration is the highest acceleration resulting from an excitation, it gives no indication as to the duration of time that the system is subjected to this level of acceleration. In contrast, the RMS acceleration represents the average measurement of an acceleration-time history, as expressed by Davis *et al.* (2014) and Sa *et al.* (2017)

$$a_{\rm rms}(t) = \sqrt{\frac{1}{N} \sum_{i=1}^{N} a_i^2(t)}$$
(3)

where  $a_{rms}(t)$  is the rolling RMS acceleration at time *t*; *N* is the number of acceleration data points measured between *t*-1 and *t*+1; and  $a_i(t)$  is the *i*th acceleration data point.

To improve the reliability of the results, Daubechies wavelet method (Jimenez-Alonso *et al.* 2014, Mokhtari and Mirdamadi 2018) was adopted to remove the noise from the raw data. The comparison between the raw and denoised

Table 11 The peak and RMS accelerations at each measuring point along route  $A_{41}$ - $A_{49}$  (×10<sup>-2</sup>m/s<sup>2</sup>)

data are shown in Fig. 10. The peak and RMS accelerations (typical example shown in Fig. 10(b)) of the composite floor due to the walking excitations along the various routes are listed in Table 11, 12, and 13, respectively. From these tables, the maximum peak and RMS acceleration are found to be approximately equal to  $17.26 \times 10^{-2} \text{ m/s}^2$  (= 1.76%g) and  $6.48 \times 10^{-2} \text{ m/s}^2$  (= 0.66%g), respectively. All the RMS accelerations indicated in Tables 11-13 are below the vibration acceptability limit of 1.5%g specified in the AISC (Murray *et al.* 2016).

# 5.2 Crest factor β<sub>rp</sub>

The RMS acceleration is usually used to assess the vibration serviceability (Murray *et al.* 2016). The determination of RMS accelerations involves a tedious calculation process which is inconvenient to engineers. This study proposes a crest factor  $\beta_{rp}$ , as describing by Eq. (4), to facilitate the calculation of RMS accelerations.

$$\beta_{\rm rp} = \frac{a_{\rm Peak}}{a_{\rm rms}} \tag{4}$$

Based on the Grubbs' criterion contained in GB/T 4883-2008 (2008), individual  $\beta_{rp}$  factors and the average value under a detection level  $\alpha_{lev} = 0.05$  can be obtained, as summarized in Tables 14-17. For design convenience and safety,  $\beta_{rp} = 2.03$  is suggested.

#### 6. Effect of human-structure interaction

The modal parameters of the composite floor can also be determined by the walking excitations. The natural frequencies and damping ratios determined by the walking excitations are listed in Table 18. Comparisons of the mode shapes obtained by the ambient vibration and walking tests are presented in Figs. 11-13. The table and figures show that the modal parameters determined by the ambient vibration and walking excitations are not exactly the same. Some significant differences are noted. The main reason for this is that the walk behaviour of a person will influence the vibration characteristics of a long span and light-weight floor (Shahabpoor *et al.* 2016), i.e., having the effect of human-structure interaction.

Table 18 Modal properties of the composite floor under different excitations

# 7. Influence factor of interaction effect

To discuss the influence of sectional dimension on interaction effect, theoretical methods were used. Detailed derivation process for the analytical solution are shown in literature Cao 2017. The cross section of composite floorconsidered in this section are the same as the investigated floor shown in Fig. 2, and only the length and span (listed in Table 19) are changed. The acceleration induced be walking with interaction and without it are listed in Table 20. From the table, it demonstrates that the interaction effect will increase the acceleration response, and with the increasing stiffness of the composite floor, the interaction effect gradually decreases.

# 8. Conclusions

A comprehensive research was undertaken to study the vibration performance of the composite steel-bar truss slab (CSTS) with steel girder, where the ambient vibration and walking tests (single, dual, and triple excitations) were conducted on-site. Based on the study results, the following primary findings and conclusions are offered:

- The first three natural frequencies of the composite floor are 5.31 Hz, 6.59 Hz, and 9.46 Hz, indicating that the composite floor is relatively flexible since these frequencies are all under the recommended practical value of 10 Hz. The damping ratios for the first three vibration modes of the composite floor are 2.00%, 0.50%, and 0.60%, all below the AISC suggested limit of 2.00% for bare floors.
- The natural frequencies of the composite floor obtained from the theoretical or numerical method are very different from the experimental results for the boundary condition CCCC (i.e., all four edges clamped), while they are relatively close to each other for the boundary condition SCSC (i.e., two opposite edges simply supported and the other two edges clamped). The minimum MAC (modal assurance criterion) value for the boundary condition SCSC between theoretical/numerical and experimental mode shapes is 0.915. Hence, the boundary condition SCSC is recommended for studying the vibration behavior of the composite floor.
- All obtained RMS accelerations due to walking appear to satisfy the AISC vibration criterion since the maximum value is 0.66%g.
- For design convenience and safety, the crest factor  $\beta_{rp}$  (ratio of peak to RMS accelerations) can be set at 2.03.
- The comparisons of modal parameters among the ambient vibration and walking tests (single, dual,

and triple excitations) show that the walking behavior of a person will influence the vibration characteristics of a long span and light-weight floor, i.e., having the effect of human-structure interaction.

• Interaction effect will increase the acceleration response, and with the increasing stiffness of the composite floor, the interaction effect gradually decreases.

#### Acknowledgments
