Abstract. Codes for structural design usually assume that the incident mean wind velocity is parallel to the ground, which constitutes a valid simplification for frequent winds caused by synoptic events. Wind effects due to other phenomena, such as thunderstorm downbursts, are simply neglected. In this paper, results of recent and ongoing research on this topic in Brazil are presented. The model of the three-dimensional wind velocity field originated from a downburst in a thunderstorm (TS), proposed by Ponte and Riera for engineering applications, is first described. This model allows the generation of a spatially and temporally variable velocity field, which also includes a fluctuating component of the velocity. All parameters are related to meteorological variables, which are susceptible of statistical assessment. An application of the model in the simulation of the wind climate in a region subjected to both EPS and TS winds is discussed next. It is shown that, once the relevant meteorological variables are known, the simulation of the wind excitation for purposes of design of transmission lines, long-span crossings and similar structures is feasible. Complementing the theoretical studies, wind velocity records during a recent TS event in southern Brazil are presented and preliminary conclusions on the validity of the proposed models discussed.

Keywords: thunderstorms; winds; downdraft; downburst; vertical profile; fluctuating velocities; mixed climate; extreme values; registered velocities.

1. Introduction

Wind action is usually a factor of fundamental importance in structural design, especially in case of large spans and light structures. Codes for structural design assume that in flat terrain the incident mean wind velocity vector is parallel to the ground, which constitutes a valid simplification for winds caused by the most frequent meteorological phenomena, such as Extratropical Storms, herein designated Extensive Pressure Systems^a (EPS) or Tropical Storms (Hurricanes, Typhoons). On the other hand, wind effects due to phenomena such as downbursts during thunderstorms (TS), and its combination with EPS winds in so-called squall lines, are simply neglected. In these events, the spatial distribution of the wind velocity on any horizontal plane, as well as its orientation, are far

* Corresponding author, Professor, E-mail: jorge.riera@ufrgs.br

^aIn agreement with many references, the authors used in previous contributions the designation Extended Pressure Systems, also denoted EPS.

from uniform. Thus, *TS* wind fields differ significantly from models implicit in current codes, rendering the applicability of the latter to large constructions highly questionable. Moreover, *TS* wind records cannot be regarded as samples of a *stationary* random process and it seems unlikely that the along-wind *fluctuating velocity* components are governed by surface roughness, as in case of *EPS* or synoptic winds. Since the vertical velocity profiles are also different, both static and dynamic methods of analysis of tall, flexible structures subjected to wind action presently in use are not adequate to model the excitation due to *TS* events.

In temperate latitude regions *not affected by tropical cyclones*, while roughly nine out of ten maximum annual velocity records at the standard 10m observation height occur during *EPS* events, extreme winds for design periods longer than about ten years are typically caused by *TS* events. In fact, Riera *et al.* (1977) pointed out more than a quarter of a century ago the need to assess the probability distribution of extreme *thunderstorm* wind velocities, sustained by the premise that the probability distribution of the maximum annual *TS* wind velocity at the reference 10m height must be different from the distribution functions that describe the probability of occurrence of winds caused by extratropical or by tropical storms. Thom (1967) had earlier proposed to deal with mixed populations of *EPS* and tropical storm winds by resorting to a combined probability distribution $P_V(v)$. Later, Riera and Nanni (1989) confirmed, using data from 14 meteorological stations in southern Brazil that extreme annual *EPS* and *TS* winds are characterized by different probability distributions and that *TS* winds govern the low probability region.

The frequency and magnitude of damage caused by thunderstorms, on the other hand, called the attention of engineers engaged in transmission line design and maintenance. In fact, according to CIGRÉ (2002), more than 80% of the transmission line tower failures due to wind action in temperate climates are caused by thunderstorm winds. This evidence confirms the importance of *TS* winds in structural design, and justifies the growing interest in the phenomenon, which actually begun in aeronautical engineering. In this paper, a simplified model of the 3D wind field caused by a *TS* downdraft proposed by Ponte and Riera (2005) for *engineering applications* is described. The model accounts for the transient nature of *TS* winds and permits introducing the velocity *fluctuating* components associated with turbulence. An application of the model to simulate the mixed wind climate in regions where both *EPS* and *TS* winds occur is described next. Simulations of this type are useful for purposes of design or risk analysis of transmission lines, long-span crossings, cable-stayed bridges and similar structures and *necessary* when long time records at the site of interest are unavailable. In this context, studies are currently in progress to simulate the extreme wind climate in large areas in the Amazon basin, in which no meteorological ground station exists. Finally, the overview of recent developments and current research in Brasil is completed with the presentation of velocity records obtained during a *TS* event in southern Brasil.

2. Recent Brazilian studies related to *TS* winds

In previous papers, Ponte (2006) and Ponte and Riera (2007) describe a non-stationary model of the wind field in a *TS* event, which is formulated in terms of meteorological variables, such as the height over the ground surface of the bottom of the causative cumulonimbus cloud, the diameter of the downdraft cylinder or the pressure drop, for which scarce data is available and no probabilistic model known to the authors exists. Nevertheless, the potential applications of these models, both for design of special engineering constructions and for wind climate simulations, are quite large.

The scheme mentioned above allows, for example, the generation by Monte Carlo simulation of all the meaningful events causing high winds along an entire transmission line during its lifetime. Note that in each loading case no additional simplifying assumptions concerning wind orientation, spatial distribution of the velocity or storm duration would be necessary. In connection with extreme velocity predictions at sites of interest and structural reliability assessments, an interesting use of the model is the simulation of extreme annual wind velocities, in terms of meteorological variables that are generally available, such as the number of *EPS* or *TS* events per year at the location of interest. This allows the estimation of the probability distribution of the wind velocity at sites that are distant from meteorological stations or where only short duration records are available.

By way of illustration, the simulation of extreme annual wind velocities caused by *TS* events at the standard 10m reference height at two sites in southern Brazil is described below, after Ponte and Riera (2010). The probability density functions obtained by simulating 50 years of record are compared with predictions based on actual observations at meteorological stations located at the selected sites, analyzed by Riera and Nanni (1989) and Riera *et al.* (1989). It is shown that the differences between both approaches are compatible with the expected statistical errors and that the proposed model may be used in engineering applications. It is nevertheless obvious that the proposed model can be improved by new data on the relevant random variables as well as in the description of the wind field itself. These improvements or eventual corrections require the contribution of specialists in related areas, such as boundary layer meteorology, computational meteorology and fluid dynamics, and it is hoped that this paper will promote such cooperation.

3. Probability distribution of extreme annual TS wind velocity

Three decades ago, Riera *et al.* (1977) proposed, in agreement with Gomes and Vickery (1976), to assess the probability distribution of extreme thunderstorm (TS) wind velocities, expecting that it would be different from the distribution functions that describe the probability of occurrence of synoptic winds caused by extratropical storms, herein designated *extensive pressure systems* (EPS) or by tropical storms. In fact, Thom (1967) had earlier proposed to deal with mixed populations of *EPS* and tropical storm winds by resorting to the combined probability distribution $P_V(v)$

$$P_V(v) = P_E \exp[-(v/\beta)^9] + P_T \exp[-(v/\beta)^{4.5}] \quad (1)$$

in which P_T denotes the frequency of occurrence of tropical cyclones in the 5° longitude-latitude square under consideration and $P_E = 1 - P_T$. Thom (1967) assumed the universal validity of Eq. (1), which requires, in a general case^b, the estimation of P_T and β . Gomes and Vickery (1976), in turn, had suggested that the distribution of maximum annual wind velocities caused by *TS* events should be related to the mean number of storms per year n_s , proposing on the basis of observations at an Australian meteorological station the adoption of a Fisher-Tippett Type I distribution (Gumbel). Riera *et al.* (1977) proposed to assess annual extreme *TS* wind velocities by adopting a Fisher-Tippett II (Frechet) distribution with parameters

^bThe addition of probabilities in equation (1) requires that the events be mutually exclusive, a condition that is not satisfied, in general, by *extreme* wind events. For example, the event that X m/s is exceeded during an EPS can occur in the same year as the event that X m/s is exceeded in a thunderstorm

$$\beta = 12.66 + 3.76 \ln n_s \text{ (m/s)} \quad (2)$$

$$\gamma = 3.36 + \ln n_s \quad (3)$$

It is recognized now that the *isolated* TS storm is less damaging than those occurring in a squall-line, in which a sum of effects takes place. Thus, Eqs. (2) and (3) would have restricted applicability. Riera and Nanni (1983) confirmed later that *EPS* and *TS* extreme annual wind series *do present* different probability distributions. When the registered velocities are classified according to their origin, in this case either *EPS* or *TS*, and angle of incidence, extreme type I distributions best fit the available series recorded at 8 Brazilian meteorological stations.

In spite of the overwhelming evidence concerning the relevance of *TS* winds in structural design, the subject has received due attention only in the area of overhead transmission lines (AS1170.2, 2002 ; AS/NZS 7000, 2010; ASCE Manual 74; CIGRÉ TB256, 2004; CIGRE TB 350. 2008). In these references, *TS* winds are included together with tornado winds within the broader classification of *High Intensity Winds (HIW)* .

4. Model of the wind field during stationary downdraft

The model of the downdraft during a *TS* event described by Ponte and Riera (2007) was adopted in this study. Readers interested in comparisons of the model predictions with other formulations or field observations may consult the reference cited above. It is assumed that, in case of a stationary cumulonimbus cloud, the wind field is axisymmetric and depends on the following physical parameters: pressure drop, background wind velocity, direction of background wind, height from level to the cloud anvil center, ratio of cloud base and characteristic time of the storm, which are herein considered random variables.

A similar set of assumptions was adopted in wind tunnel studies of the phenomenon, in which a downburst was modelled by a stationary jet impinging on a flat surface (Wood and Kwok 1998) In this context, Riera and Rocha (1998) proposed an axi-symmetric velocity field based on a solution developed by Zhu and Etkin (1985) . Similar models are due to Holmes and Oliver (2000) and Chen and Lechford (2004). The axi-symmetric velocity field constitutes a satisfactory approximation to a stationary downdraft and was adopted with some simplifications in the *TS* transient wind field

(From University of Illinois - WW2010 on- line guides)

Fig. 1 Flow lines in TS (initial contact)

(From University of Illinois - WW2010 on- line guides)

Fig. 2 Flow lines in TS

proposed by Ponte and Riera (2007). The latter is a basic tool in the simulation study discussed herein and will thus be summarized in the following. It is assumed that the causative cumulonimbus cloud is a circular cylinder with vertical axis. The base of the cylinder, i.e., of the cloud, is at height h above ground level. The flow lines are also assumed to be axisymmetrical in relation to the cloud vertical axis.

The tangential velocity at height z along a flow line may be obtained applying Bernoulli's Theorem for heights h and z above the ground, in which dp denotes a pressure differential while ρ is the specific mass, modeled by the exponential function (5)

$$V_t = \left[2 \int_z^h dp / \rho \right]^{1/2} \quad (4)$$

$$\rho(z) = \rho_o \exp(-\beta z) \quad (5)$$

In the range $0 < z < 10000$ m the parameters in Eq. (5), estimated using data from Donald and Fox (1995), are $\rho_o = 1.019 \text{ kg/m}^3$ and $\beta = 0.0001$. The pressure difference is assumed to vary linearly from zero at height h to ΔP_o at height z

$$p = \Delta P_o (1 - z/h) \quad (6)$$

introducing Eqs. (5) and (6) in Eq. (4) and solving the integral, the following expression for the tangential velocity is finally obtained

$$V_t = [(2 \Delta P_o) / (h \rho_o \beta)]^{1/2} [\exp(\beta h) - \exp(\beta z)]^{1/2} \quad (7)$$

Furthermore, available information suggests that the total pressure drop ΔP_o ranges between 100 and 500 Pa, although no data was found to fit a probability density function to ΔP_o , which must then be modeled solely on the basis of its estimated maximum and minimum values. For any given value of ΔP_o , Eq. (7) allows the determination of the tangential velocity. A typical velocity-height curve is shown in Fig. 3. The axial and radial velocity components along a flow line can be determined from the equation of the latter. Zhu and Etkin (1985) presented a simplified 3-dimensional model –the so called *doublet sheet model*– based on fluid mechanics considerations. For engineering purposes, the model was simplified, maintaining the assumption of axial symmetry. In the following, the flow lines are described by Eq. (8), in which k is a constant and r is the distance to the vertical axis of the cloud.

$$z(r) = k/r \quad (8)$$

In fact, for various similar flow lines, differences in predicted velocities are marginal. For a specific flow line, the derivative of z in relation to r , denoted $z'(r)$ defines the tangent of the angle in relation to the Or axis. At point (r_p, h) , the radial and axial velocity components for any height z of interest are given by

$$V_r = V_t \{ 1 / [1 + z'^2(r_p)] \}^{1/2} \quad (9)$$

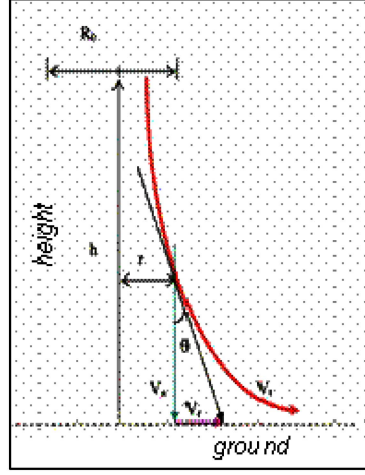

Fig. 3 Flow line in downdraft

$$V_a = V_t \{ z^2(r_p) / [1 + z^2(r_p)] \}^{1/2} \quad (10)$$

$$r = [x^2 + y^2]^{1/2} \quad (11)$$

$$\sin \theta = \{1 / [1 + z^2(r_p)]\}^{1/2} \quad (12)$$

$$\cos \theta = \{z^2(r_p) / [1 + z^2(r_p)]\}^{1/2} \quad (13)$$

in which θ denotes the angle between the tangent to the flow line and the vertical axis Oz . Finally, it results

$$V_a = V_t [r_p^2 h^2 / (r_p^2 h^2 + r^4)]^{1/2} \quad (14)$$

$$V_r = V_t [r^4 / (r_p^2 h^2 + r^4)]^{1/2} \quad (15)$$

The velocity components in the direction of the coordinate axes are given by

$$V_x = V_t \sin \theta \cos \beta = V_r \cos \beta \quad (16)$$

$$V_y = V_t \sin \theta \sin \beta = V_r \sin \beta \quad (17)$$

$$V_z = V_t \cos \theta = V_a \quad (18)$$

In which β denotes the angle between the projection of the flow line on a horizontal plane and the Ox axis.

5. Background wind and translational velocity of causative cloud

In most cases, the causative cloud is carried by the general circulation in the region, herein designated *background wind*. It is assumed that the background wind has constant velocity and the same orientation throughout the region in which the wind climate will be simulated, in this study a

400 km² square area. In rarer occasions, however, mature cumulonimbus clouds are carried by storm fronts. This gives rise to so-called *squall lines*, which result in higher wind intensities because the velocity resulting from the downdraft adds up to the translation velocity of the storm. In temperate latitudes, like southern South America, these fronts are due to extended pressure systems (EPS), i.e., extratropical cyclons, characterized by diameters that vary between around 400 and 1000 km. In view of those dimensions, it may be assumed that the velocity within the reference area, only 20 km wide, is uniform, although characterized by a probability distribution and turbulence that differ from those assigned to the background wind caused by general circulation. It is also assumed that the resulting velocity vector at any point may be obtained as the vectorial sum of the stationary velocity vector, determined in Section 4, and the background or EPS wind velocity vector. If V_o denotes the modulus of the wind velocity vector at a point, which forms an angle γ with the Ox axis, then the resultant velocity components in a reference cartesian coordinate system (xyz) are given by

$$V_{Rx} = V_r \cos \beta + V_o \cos \gamma \quad (19)$$

$$V_{Ry} = V_r \sin \beta + V_o \sin \gamma \quad (20)$$

$$V_{Rz} = V_z \quad (21)$$

The wind velocity field described above assumes that the downdraft flow from the causative cloud is stationary. The resulting velocity amplitudes are thus upper bounds of the actual amplitudes, which vary with time defining a transient process. Following Holmes and Oliver (2000), the evolution of the wind velocity with time is herein represented by the equations

$$V(t) = 1.58 V_t [1 - \exp(-t/T)] , \text{ for } t \leq T \quad (22)$$

$$V(t) = V_t \exp [-(t - T) / T] , \text{ for } t > T \quad (23)$$

T denotes the storm *characteristic time*, defined as the time lapsed from the initiation of the transient wind to the instant at which the velocity attains its maximum value (See Fig. 4).

Fig. 4 Evolution of the wind velocity with time in a stationary TS event (After Holmes and Oliver 2000)

6. Vertical profile of horizontal velocity component

The *vertical profile of the horizontal component* of the wind velocity field at a given location has great interest in structural engineering, since it has a direct influence on the distribution of horizontal wind forces along the height of a construction at the location under consideration. The model proposed herein predicts a vertical profile, for a stationary cloud, similar to the graph of radial velocities shown in Fig. 6. It may be seen that the profile depends on the position of the vertical axis of the cloud in relation to the location of interest. Also note that the velocity distribution illustrated by Fig. 6 does not take into account the roughness of the terrain, i.e., the existence of a boundary layer that would imply a decrease of the velocity as we approach the ground. Chen and Letchford (2004) recently presented a critical evaluation of models of the vertical profile for *TS* winds available in the literature. Oseguera and Bowles (1988) propose an empirical Eq. (24) for the average horizontal velocity caused by a downdraft:

$$V(z) = (\lambda R^2 / 2r) \{1 - \exp[-(r/R)^2]\} [\exp(-z/z_c) - \exp(-(z/z_d))] \quad (24)$$

In which λ denotes a scale factor with dimension $[T]^{-1}$, z_d a characteristic height (inside the boundary layer), z_c a characteristic height (outside the boundary layer), r the distance to the vertical axis of the downdraft cylinder and R the characteristic radius of the downdraft cylinder. Vicroy (1992), suggests the following equation for the velocity vertical profile

$$V(z) = 1.22 V_{max} [\exp(-0.15 z/z_m) - \exp(-3.2175 z/z_m)] \quad (25)$$

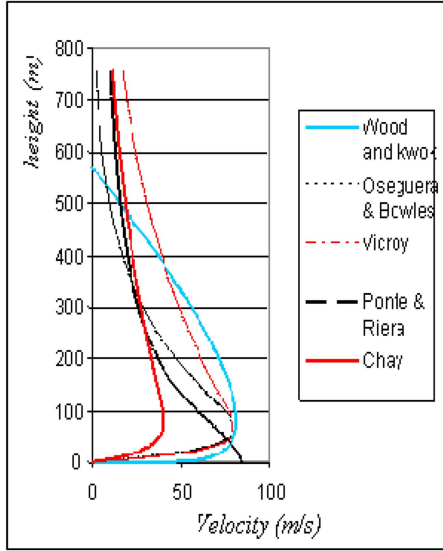

In Eq. (25), V_{max} is the maximum velocity in the profile, while z_m denotes the height at which the maximum velocity occurs. A third model is due to Wood and Kwok (1998)

$$V(z) = 1.55 V_{max} (z/z_0)^{1/6} \{I - \Phi[0.7(z/z_0)]\} \quad (26)$$

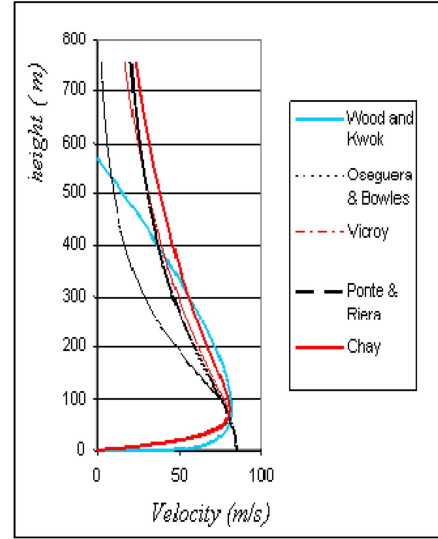

In Eq. (26), z_0 represents the height where the speed is half the maximum value while Φ denotes the error function. Chen and Letchford (2004) built comparative profiles of the models listed above. More recently, Chay *et al.* (2006) modified Eq. (27) suggested by Vicroy (1991) for the vertical profile

$$V(z) = (\lambda r/2) [\exp(c_1(z/z_m)) - \exp(c_2(z/z_m))] \exp[(2 - (r^2/r_p^2)^\alpha)/2\alpha] \quad (27)$$

In which λ is a scale factor, α , c_1 and c_2 are constants, r is the radius r_p the radius at which the maximum velocity occurs, z_m the elevation at which the maximum velocity occurs and z a generic elevation. Figs. 5 to 6 show vertical profiles proposed in the literature, which are compared with profiles predicted by the proposed model. The graphs were normalized to present in Fig. 6 a common velocity of 80 m/s at 67 m height. It may be seen that although the various models reflect specific features of *EPS* winds, such as the fact that the maximum velocity is attained at a height usually below 100 m and that the velocity decreases for higher elevations, they present perceptible differences. The proposal of Ponte and Riera (2007) approaches the model of Oseguera and Bowles (1988) when the distance to the cloud axis is around 100 m. When the distance is about 200 m the model predictions approach Vicroy's (1992) equation. The model predictions are not close to Wood

(from Ponte and Riera 2007)

Fig. 5 Vertical profile at radius $r = 100$ m

(from Ponte and Riera 2007)

Fig.6 Vertical profile at radius $r = 200$ m

and Kwok (1998) results for any value of r . This poor correlation is attributed to the fact that the latter is based on experimental observations in wind tunnel, which do not faithfully reflect the field situation (Chen 2004). The evidence clearly illustrate the fact *TS winds are not characterized by a generic vertical velocity profile*, but by a family of profiles, depending on the distance from the location of interest to the path of the storm. In addition, since the causative cloud is typically in motion, the issue is further complicated by the fact that at least one additional factor should be considered, which is the ratio between the translational velocity of the cloud and the downdraft wind velocity.

7. Fluctuating velocity component

Under usual conditions, atmospheric flow in the lower boundary layer is turbulent, presenting fluctuations of the wind velocity around an average value. The magnitude of the velocity vector in the direction of the flow may be written as

$$V(t) = V_m(t) + \Delta V(t) \quad (28)$$

In which $V(t)$ denotes the instantaneous velocity at time t , $V_m(t)$ the mean velocity and $\Delta V(t)$ the fluctuating longitudinal velocity component. When the flow is stationary, the mean velocity V_m does not depend on time. In such case, Eq. (28) can alternatively be written in the form:

$$V(t) = V_o [1 + I\phi(t)] \quad (29)$$

In which V_o is a mean reference velocity, I the intensity of turbulence and $\phi(t)$ a stationary random

process with zero mean and unitary standard deviation. The intensity of turbulence is defined as the quotient between the standard deviation of the longitudinal velocity fluctuations and the mean velocity[26]. The random process $\phi(t)$ is defined by its power spectral density function (psdf), for which a number of models have been proposed in the technical literature, such as those due to Davenport, Von Karman, Kaimal and Harris (Simiu and Scanlan 1996). However, all these spectral density functions are only applicable when vertical stability of the atmosphere prevails and the turbulence in the lower boundary layer results mainly from the interaction of the flow with the rough soil surface. Note that a minimum stretch is needed to develop a given profile and turbulence intensity. The length of this so-called *exposure terrain* is of the order of one kilometer or more, condition that is not satisfied by *TS* winds, in which the flow lines remain close and approximately parallel to the ground for a few hundred meters. Thus, there seems to be no reason to expect that the psdf of the velocity fluctuations in *TS* winds will be satisfactorily modeled by the functions normally employed for *EPS* winds.

A purely empirical approach to the problem seems of little use, on account of the large number of factors discussed in connection with the vertical profile, which should also influence the turbulence spectra. However, Ponte and Riera (2007) conducted a preliminary analysis of *TS* wind records, which revealed peaks in the psdf's of the fluctuations, in the frequency band between 0,05 and 0,55 Hz, with no prevailing frequency. A very simple model for the longitudinal turbulence in *TS* events a band-pass white noise, with frequency limits as quoted above, was then adopted. In order to simulate such process in preliminary applications, the velocity fluctuations were expressed as $V_o I \phi(t)$, with

$$\phi(t) = A_1(t) \sin(\omega_m t) + A_2(t) \cos(\omega_m t) \quad (30)$$

$$A_1(t) = \sin(\omega_L t) \quad (31)$$

$$A_2(t) = \cos(\omega_L t) \quad (32)$$

In which A_1 and A_2 are functions of the lower cut-off frequency ω_L , while ω_m denotes the median frequency between ω_L and the upper cut-off frequency ω_u , that depends on the power spectral density function to be simulated. Introducing Eqs. (31) and (32) into Eq. (30) leads to the equivalent generic equation

$$\phi(t) = a \cos[(\omega_m - \omega_L)t + \theta] \quad (33)$$

in which θ is a random phase angle characterized by a uniform probability distribution function within the $[0, 2\pi]$ interval.

8. Random variables in simulation of wind series

The simulation of annual maximum wind series at predefined locations requires the specification of the following data:

- Geographic region of interest.
- Dimensions of area in which the simulation will be performed
- Mean frequency of *TS* events in the region
- A probabilistic model of the pressure drop

- Probability distribution of intensity and orientation of background wind
- A probabilistic model of the characteristic time of TS events
- A probabilistic model of height from ground to cloud .

The topics listed above are discussed in this section in connection with the numerical examples, which aim at demonstrating the feasibility of the approach.

Geographic region of interest. Riera and Nanni (1989) present statistical data on extreme wind velocities collected at meteorological stations in South-Eastern Brasil. The recorded velocities were classified as due to *EPS* or *TS* events and processed separately, thus offering reliable direct observational evidence. From those records, Porto Alegre and Uruguaiana were selected by Ponte and Riera (2010) as test cases to apply the simulation procedure discussed herein.

Dimensions of area in which the simulation will be performed The area considered was a square with sides 20 km long. The site where the wind climate will be simulated is located at its centre. The dimensions of the region should be large enough to assure that the probability of a storm path that originates outside the region reaches its centre is negligibly small. Since the shortest distance from the edge of the square to its centre is 10km, this first requirement would be thus satisfied. The second factor is related to the assessment of the frequency of occurrence of *TS* events in the region, which is an importante climatological factor that led to the same length of the sides of the square. In fact, the region considered might also be circular with 10 km radius

Mean frequency of TS events in the region. The simulation procedure requires the specification of the mean number of *TS* events per year in the region under consideration. In the examples this number was determined from data on isoceraunics in Brazilian code NBR 5419 (1991). The information is generally available because of its application in electric power transmission. Essentially, it consists of the records of the number of *thunder events*, heard by operators at meteorological stations. Since thunders always occur in connection with fully developed *TS* events, it may be admitted with little error that the *number of isoceraunics equals the number of TS events that may be heard by the operator at the meteorological station* Thus, admitting that the operator generally misses –that is, does not take notice of– thunder when the causative cloud is farther than about 10 km, the choice of the dimensions indicated above, allows adopting the number of isoceraunics as indicative of the mean yeraly number of *TS* events in the region of interest Table 1 shows the mean number of *TS* events per year in the examples.

Pressure drop in thunderstorms. In Porto Alegre, records of pressure drops of up to about 7 milibars per hour (700 N/m^2) can be found. Caracena *et al.* (1977) suggest that the pressure drop in microbursts varies from 2.4 mb to 5 mb (240 N/m^2 to 500 N/m^2), but no indication is given concerning its probability density. In the ensuing simulations a *Gumbel* – (Type I Extreme Value Distribution) with shape an scale parameters $\alpha = 50 \text{ N/m}^2$ and $\gamma = 100 \text{ N/m}^2$, respectively, are adopted. The resulting probability density function is shown in Fig. 7.

Characteristic Time. The characteristic time is the storm duration from its beginning to the moment when the velocity reaches its maximum value. The authors did not find any statistical data

Table 1 Isoceraunics in Porto Alegre and Uruguaiana

| Station | Mean number of TS events / year |
|--------------|---------------------------------|
| Porto Alegre | 20 |
| Uruguaiana | 30 |

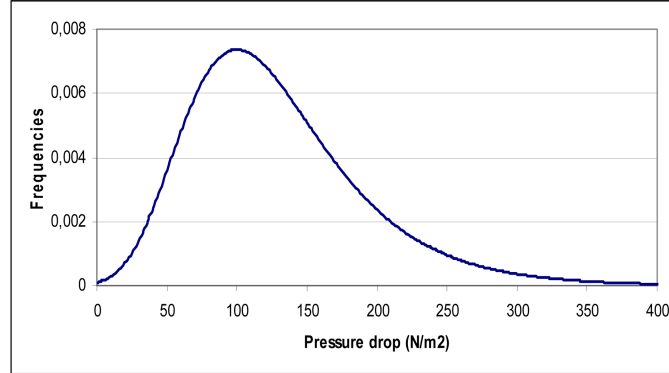

Fig. 7 Probability density function of pressure drop in a random TS event

Table 2 Data from Brazilian meteorological stations: characteristic time T

| Station | Date | Characteristic time T | Maximum velocity |
|------------------|----------|-------------------------|------------------|
| Passo Fundo | 17/10/90 | 330 s | 15.6 m/s |
| Passo Fundo | 10/02/89 | 480 s | 15.6 m/s |
| Passo Fundo | 20/12/87 | 510 s | 18.1 m/s |
| São Luiz Gonzaga | 01/07/93 | 180 s | 25 m/s |
| São Luiz Gonzaga | 11/11/88 | 570 s | 25.8 m/s |
| São Luiz Gonzaga | 05/01/85 | 210 s | 20.8 m/s |

on the subject in the literature. Thus, for simulation purposes available TS records from two Brazilian meteorological station were resorted to. The data is shown in table 2 . The mean value and the standard deviation for the records shown in Table 5.2 are $\mu = 380$ s and $\sigma = 164$ s. The parameters of an extreme type I distribution may be calculated by

$$\mu = \gamma + 0.577\alpha \quad (34)$$

$$\sigma = 1.282 \alpha \quad (35)$$

$$\alpha = 127\text{s} \quad (36)$$

$$\gamma = 306 \text{ s} \quad (37)$$

Probabilistic model of the background wind velocity. In the simulation process, the modulus of the background wind velocity at the reference 10 m height was assumed to present a Weibull distribution with shape parameter $\beta = 2.5$ and location parameter $\theta = 3.0$ m/s . These values were obtained from 50 years records reported in the Rio Grande do Sul Eolic map. Since no reference was found concerning the background wind orientation, a uniform distribution between 0 to 2π was adopted for the direction of background winds

Height of cumulonimbus cloud . No statistical data on this parameter was found by the authors. There seems to be no indication of a possible dependence of the parameters on the geographical

location. For middle latitudes, as is the case of the stations considered in the examples, a normal distribution with mean $\mu = 10000$ m and standard deviation $\sigma = 500$ m was adopted.

9. Simulation method

A procedure to simulate series of maximum annual wind velocities was programmed in MatLab. The simulation adopted the parameters described in section 5 with the results shown in Table 3. The table presents the parameters obtained from series of 50 maximum annual wind velocities. The selected probability distribution, the Kolmogorov and Smirnov (KS) factor for goodness of fit and the mean number of storms per year for each studied location are presented in the table.

Comparison of simulated records with available observations. The probability density functions of maximum annual TS winds at the two selected meteorological stations obtained by simulation were compared with predictions based on actual records Riera *et al.* (1989). These references furnish maximum wind velocities for eighth orientations (octants). Tables 3 and 4 show the mean, standard deviation and extreme Type I (Gumbel) parameters for TS wind velocities.

Using data from each octant, it is possible to determine the maximum velocities for each station, regardless of wind orientation, indicated in Table 5. The density function for the maximum velocities will also be Gumbel with the following parameters:

$$\gamma = \alpha \ln \sum \exp(\gamma_i / \alpha) \quad (38)$$

$$\alpha = S \alpha_i / 8 \quad (39)$$

Table 3 Simulation results

| Station | TS events per year (n_s) | Mean Value (m/s) | Standard deviation (m/s) | Location parameter γ | Shape parameter | Distribution model | KS Factor DC |
|--------------|------------------------------------|--------------------------|----------------------------------|-----------------------------------|--------------------|-----------------------|-----------------|

Fig. 9 Probability density functions for maximum annual TS winds (Uruguaiiana)

in which γ_i , α_i , denote the parameters for each octant i ($i = 1, \dots, 8$) and the sum extends from 1 to 8.

The probability density functions of the maximum annual TS wind velocities at the two meteorological stations considered in this paper, obtained by simulation and direct observation, are shown in Figs 9 and 10. The differences between both sets of results are of the same order as the statistical errors in the latter, which are not negligible due to the short duration of the records (28 years in Porto Alegre and 21 years in Uruguaiiana) and may be considered compatible. In summary, a robust model for the wind velocity field during thunderstorms was proposed in the paper, taking into consideration all features of the phenomenon considered relevant for the design of structures subjected to wind action. The model predictions are compatible with available evidence concerning, for example, storm duration or vertical velocity profiles. Moreover, the formulation of the model requires a number of parameters that have ranges of variation reasonably well defined in meteorology, allowing risk assessments even in situations in which scarce data is available for the

region of interest. Presently, studies are being conducted to estimate the risk of intense TS winds in the Amazon region, which are needed for the design of TL crossings in uninhabited areas.

10. Analysis of a recorded downburst event

The wind fields in extra-tropical cyclons as well as in tropical storms may be modeled, for purposes of structural analysis and design, as stationary random processes, in which the mean wind velocity at the reference 10 m height is assumed constant over a large area. On the other hand, downburst winds and tornados are characterized by a pronounced spatial variability and by their transient nature. In consequence, records of *TS* winds are scarce and much needed to validate or improve available theoretical models. Experimental data were recently reported by Orwig and Schroeder (2007) and Holmes *et al.* (2008), including comprehensive assessments of the Lubbock rear-flank downdraft of 2002. One additional case, presently under analysis, will be discussed next. The measurements were conducted at a 40 m high tower of the Universidade de Passo Fundo (UPF), Rio Grande do Sul, Brasil, meteorological station. Cup anemometers are installed at levels 10, 20, 30 and 40 m above ground. The wind orientation is measured only at elevation 40 m. Fig. 10 shows a Google plan view of the station and surrounding area, as well as the location of the tower of the UPF TV station, destroyed during a TS event on November 9, 2007. The meteorological station is situated at $28^{\circ} 13' 35''$ S and $52^{\circ} 23' 03''$ W, at an altitude of 692 m.

Fig. 11 presents a view of the velocity records at 20, 30 and 40 m, respectively, while Fig. 12 presents the wind orientation, recorded at 40 m. It may be clearly seen that the flow was initially nearly stationary - the background wind velocity at 40 m height remains well below 5 m/s during the minutes preceding the storm and with constant orientation- meaning that the causative cloud approaches the station slowly (Puglia and Ramires 2010). Moreover, up to around $t = 500$ s there is no indication of the arrival on the downburst, which earlier affected only layers *below* the 40 m level.

Note that the time scale of the velocity records is out of phase with the scale of the orientation record, in which the *TS* wind front may be seen to arrive at $t = 375$ s . It seems also evident that

Fig. 10 Plan view of meteorological station (center down) as well as UPF TV station

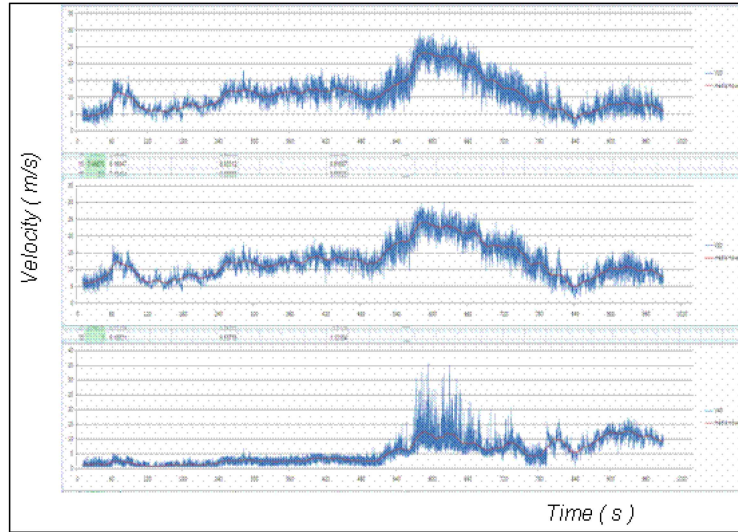

Fig. 11. Wind velocity records at 20, 30 and 40 m height. The instrument at 10 m was out of order

Fig. 12. Instantaneous orientation of the wind horizontal component at 40 m height

between $t = 575$ s and $t = 735$ s the operation of the anemometer installed at 40 m was disturbed by the strong vertical velocity components of the downburst. This will require wind tunnel measurements with the middle plane of the cup anemometer inclined in relation to the wind orientation, to assess the influence of the orientation.

Finally, another issue that requires further assessment is related to the *fluctuating components* of the velocity field. A *mean velocity* record was determined by applying to the records a moving average operator over a period $\Delta t = 30$ s and the fluctuating component defined as the difference between the measured velocities and the mean. A plot of the power spectral density function of the fluctuating component in the interval between 360 and 985 s, assumed to be a *sample of a stationary random process*, is shown in Fig. 13. The rms value of the fluctuating velocity for this record is about 1.7 m/s. Although the above results corresponds to just one record at a single weather station, it suggests that the clipped white noise model suggested by Ponte and Riera (2007)

Fig. 13. Power spectral density function (psdf) of fluctuating component at 20 m level ($\Delta t = 30$ s)

may be improved by a triangular or an exponential psdf. It is finally observed that, in agreement with previous evidence registered at the same station, the velocity time-histories at elevations 20 and 30 m are highly correlated, which also suggests that velocity fluctuations are, primarily, *not caused* by surface roughness. Experimental data on TS events were recently reported by Orwig and Schroeder (2007) and by Holmes *et al.* (2008), which include comprehensive assessments of the Lubbock rear-flank downdraft of 2002.

11. Conclusions

An overview of recent and ongoing research at LDEC, UFRGS, Brasil, on extreme winds caused by downbursts (*TS* winds) was summarized in the paper. Initially, a semi-empirical model of the wind field in a downburst is described, which aims at the consideration of meteorological variables in the simulation of such events, specially the features of the cumulonimbus cloud that causes the downdraft. The use of the model to simulate the extreme wind climate at two locations in southern Brasil, where data on annual extreme velocities classified according to the storm type are available, proves that the approach is feasible and might be considered in structural reliability assessments elsewhere. These developments are much needed in regions like the Amazon basin, for example, where large transmission line crossings are presently being designed, while meteorological records are very scarce or non-existent. In order to emphasize the need of evaluating the performance of available models to predict wind effects on structures, experimental evidence on the wind field during a *TS* event presently under analysis is finally reported.
